ABSTRACT
Twelve (Experiment I) and four (Experiment II) multiparous dairy cows seronegative to pestivirus were selected and randomly assigned to either a control group which did not become infected or a treatment group in which all cows became infected following intranasal inoculation 4 days before AI. The experimental induction of infection was carried out with V ml of non-cytopathic pestivirus (BVD virus) suspension containing \( 2 \log_{10} \text{TCID}_5 \) /ml (Experiment I) and \( 3 \log_{10} \text{TCID}_5 \) /ml (Experiment II). In both experiments, the cows were superovulated on day 1 of the cycle using the standard procedures. The cows in Experiment I were artificially inseminated at 72 and 78 h after the onset of estrus and a non-surgical ova/embryo collection was performed 7 days after AI. In Experiment II, the cows were slaughtered on day 7 after superovulation-induced estrus and the ovaries submitted for gross and histopathological examination including immunohistochemistry. Mean \((\pm SE)\) number of ovulatory sized follicles on day of AI and corpora lutea palpated on day 7 after AI were significantly \((p<0.05)\) higher in control un-infected cows compared to that of the pestivirus infected cows \((7.1\pm1.7, 7.4\pm1.4\) and \(7.1\pm1.7, 7.4\pm1.6\)), respectively. On histopathological examinations, the mean \((\pm SE)\) number of unovulated luteinised follicles \((\geq 8 \text{mm in diameter})\) present on the ovaries of the control cows on day 7 after estrus was \(8.4\pm1.3\) compared to \(12.2\pm2.4\) for the infected cows. Further, many corpora lutea in the ovaries of infected cows had a hypoplastic or atrophic wall. In conclusion, the present study demonstrated that pestivirus infection during the period of final growth of preovulatory follicles results in a disturbance in ovulation and development of corpus luteum leading to a poor superovulatory response in multiparous dairy cows.

Key words: pestivirus infection, superovulation, immunohistochemistry, ovary, dairy cows
INTRODUCTION

Non-cytopathic type bovine pestivirus infection is prevalent in the cattle populations of many countries (see Kafi). In Iran, the prevalence of seropositive cows to pestivirus infection was reported between 30% to 70% percent (Sedigi-Nezhad). Cattle undergoing pre- or postnatal infections are associated with a variety of disease syndromes that include immune suppression, congenital defects, abortion, and mucosal disease and, importantly, disruption of reproductive functions (see Kafi).

It has been demonstrated that spontaneously infected (Virakul et al.) or experimentally (McGowan et al.) induced pestivirus infection at approximately the time of artificial insemination (AI) significantly lower conception rate in dairy cattle. Field studies (McGowan et al.; Rufenacht et al.) have also shown that pestivirus infection is a cause of reproductive loss in dairy cows. The adverse effect of bovine pestivirus infection on the final growth of ovulatory follicles was initially reported in superovulated Holstein heifers by Kafi et al. Later, it was shown that acute pestivirus infection disturb follicular development (Grooms et al.) and corpus luteum development (Fray et al. and McGowan et al.) following experimental infection of seronegative cattle with a non-cytopathic bovine pestivirus.

The aim of the present study was to determine a) the superovulatory response of dairy multiparous Holstein cows experimentally infected with a non-cytopathic isolate of bovine pestivirus (Experiment I). Further, the morphologic changes and the distribution of pestivirus antigens in ovarian structures of the infected cows were evaluated using gross and histopathological examinations including immuno-histochemical examinations (Experiment II).

MATERIALS AND METHODS

Experiment I

Twelve multiparous Holstein cows, aged 4 to 9 years, were selected from a brucellosis free herd. To confirm that they are pestivirus antibody-free, all cows were bled before commencing the experiment. The cows were checked to determine their body condition scores (based on 1 to 5), all animals were in a range of 2 to 3 of condition score two weeks before breeding. After a general examination, the cows were randomly divided into two control and treatment groups, and placed in two paddocks. The cows were being fed by good quality pasture grass and supplemented based on the pasture condition.

Experimental infection: Inocula were prepared shortly before use by adding 1 ml of bovine serum to 2 ml of virus culture media containing 4.5 log TCID/ml to adjust final inoculum to 6 log TCID/ml of non-cytopathogenic pestivirus. The serum inoculum contained an Australian strain of non-cytopathogenic bovine pestivirus (BVD-type) isolated from a persistently virus carrier Angus cow (McGowan et al.). All cows in the treatment group were infected by intranasal installation of 6 ml of the inoculum (one ml in each nostril) 3 days prior to AI. Shortly before inoculation, each cow was isolated from the remaining uninoculated cows. This way of experimental infection was previously shown to have a high reliability and further the magnitude and duration of viremia-induced is similar to that observed following natural infection (Cook et al.).

Sample collection: All cows were blood sampled 14 days before and immediately prior to virus inoculation. Also, blood sampling was
carried out every second day until day ⁴ after virus inoculation, and then on days ¹⁷, ¹⁸, ¹⁹ after virus inoculation. Blood samples were kept chilled and after clot formation, the sera were separated and stored frozen at −¹⁷°C until assayed for detection of pestivirus or antibody to pestivirus. All unfertilized and degenerate embryo were stored in straws and frozen in order to examine for isolation of virus or virus-associated antigens. The above-mentioned specimens were shipped to the veterinary laboratory of Camden (N.S.W.) for serology and virus isolation.

**Serological examination:** The sera samples were examined by Gel Diffusion Precipitin (GDP) test to detect antibody to pestivirus. Also, ELISA test was carried out to confirm the GDP test results (Kirkland et al ¹⁴⁴). **Virus isolation:** Virus isolation was carried out on ¹ ml of each serum sample collected ¹, ², ³, ⁴ days after inoculation to identify the approximate time of onset of viraemia. A second quantitative examination of serum samples was attempted to measure the titer of virus in the serum samples (Kirkland et al ¹⁴⁴). In addition, the unfertilized and degenerate embryos were examined for pestivirus.

**Oestrus synchronization and superovulation:** Oestrus synchronizaton was performed by using syncromate (SMB) implant (Intervet, The Netherlands) containing ⁷ mg of progestagen norgestomet. After rectal palpation, those cows that had an active corpus luteum, were injected with ⁵⁰ µg of cloprostenol (Prostaglandin F₂α analogue) intramuscularly to be prepared for a synchronization programme. Thus, at the time of SMB implant insertion, most cows were in luteal phase based on the findings of rectal palpation. One SMB implant was inserted on the outer surface of the ear of each cow by using the applicator (this was concomitant with intranasal inoculation of the virus in the treatment group). On day ⁷ after SMB insertion, the implants were removed and at the same time all cows received ⁵⁰ µg cloprostenol intramuscularly to have more precise oestrus synchronization. At the time of removing the implants, the animals were tail painted to aid heat detection. The cows were observed for oestrus behaviour from ⁷ hours after removing the implants and the cloprostenol injection. Using one injection of equine chorionic gonadotrophin (eCG) was considered less stressful to the cows than handling and injecting them eight times, if FSH was used. All cows received ⁵⁰ IU eCG intramuscularly on day ¹ after the induced oestrus, ⁷ days after using SMB implant, followed ⁴ hours late by an injection of ⁵⁰ µg cloprostenol i.m. to cause regression of the mid-cycle corpora lutea and induce oestrus.

**Artificial insemination:** Prior to AI, the amount of paint loss was scored and recorded. Approximately ⁴ and ⁶ hours after removing implants and cloprostenol injection, all animals were artificially inseminated twice (at ⁴ hours intervals). The frozen thawed semen used for insemination was from a Holstein pestivirus free bull of high fertility. It was examined to be free of pestivirus by seronegative sheep that was inoculated with whole blood from the bull. The sheep was then serially bled to monitor the occurrence of seroconversion. Further, whole blood from the bull was submitted for pestivirus antigen capture ELISA testing (Kirkland et al ¹⁴⁴).

**Ultrasound examination of ovaries:** Immediately prior to AI, each cow was scanned to visualize the ovarian structures using a B-mode ultrasound machine equipped with a ⁵ MHz linear array transrectal transducer (SSD, ⁵ V, Aloka Co., Tokyo, Japan). The number of follicles (≥ ¹ mm) on the right and left ovary were determined.

**Embryo collection and evaluation:** On day ⁷ after AI, a transcervical ova/embryo collection was performed. Shortly before ova/embryo collection, the number of corpora lutea on the ovaries of each
cow was determined via rectal palpation. The flushing medium used was phosphate-buffered saline (PBS) supplemented with 1% fetal calf serum (FCS) and 100 µg streptomycin per milliliter and 10 µg of fungizone. Immediately after each collection, the flushed media was searched to find ova/embryos. They were then identified, counted and evaluated by gross morphological criteria using the classification below (Elsden).

**Embryo culture:** All good quality embryos were held in the culture media at 37 °C prior to culture. Then, the embryos were cultured in Hams-F11 medium (CSL, Commonwealth, Australia) supplemented with 10% fetal calf serum in 37 °C plastic dishes in an atmosphere of 5% CO₂, 5% O₂, 90% N₂. The temperature and relative humidity of incubator were 37 °C and 85%, respectively. The embryos were morphologically evaluated 48 h. after the commencement of culture and their developmental stages were recorded.

**Experiment II**

Four Jersey cows aged 4-7 years were used in this experiment. Two days prior to commencement of the experiment the cows were blood sampled via coccygeal vein and serum or whole blood submitted for pestivirus serology and virus isolation. Then, two seropositive cows were assigned to the control group and two seronegative non-viremic cows to the infected group. The method and the timing of experimental infection for each cow in the infected group were similar to that described in Experiment I. Then, the cows in either group were treated for synchronization of oestrus and superovulation as previously described (Kafi et al.). As the cows were to be slaughtered on day 14 post-inoculation, infection was confirmed by virus isolation from plasma collected on days 3 to 5 post-inoculation. The procedure for virus isolation has been previously described (Kirkland et al.). The cows in the control and infected groups were all slaughtered on day 14 post-inoculation (4 days after superovulatory-induced oestrus). The ovaries of the slaughtered cows were then collected and several longitudinal slices (5-8 mm thickness) of tissue from each ovary were placed in 1% buffered formaldehyde. The ovarian slices contained both follicular and luteal structures. The ovarian slices were subsequently embedded in paraffin and 5 µm sections initially stained with haematoxylin and eosin.

**Immunohistochemistry:** Paraffin-embedded sections of the ovaries each cow was immunolabelled according to Swasdipan et al. Briefly, formaldehyde-fixed paraffin-embedded tissues were immunolabeled for bovine pestivirus using the bovine pestivirus-specific monoclonal antibody. Cytospin preparations of bovine pestivirus-infected and noninfected bovine tracheal cells functioned as positive and negative controls, respectively. Other controls comprised substitution of specific antibodies with nonreactive antibodies (specific for alphaviruses) and omission of reagents.

**Statistical analysis:** The differences in the mean number of ovulatory-sized follicles on day of AI, mean number of corpora lutea on day 4 after AI, mean number of recovered ova/embryos, mean number of fertilised ova and mean number of transferable embryos for each group in Experiment I were compared using a t-test. Fischer exact test was used to statistically analyse the proportions for the results of the embryo culture. All statistical analyses were carried out using SAS programs package (SAS Inc., Cary, NC, USA). The level of significance was set at p<0.05.

**RESULTS**

**Clinical observations:** During the whole period of the present study, none of the cows showed any clinical signs of disease. Further, no sign of diarrhea, increased nasal or lacrimal discharge, or
other signs related to BVD/MD were not observed following the virus inoculation.

**Experimental infection:** In Experiment I, of 9 cows in the control group, 6 cows were seropositive and 3 cows were identified seronegative before commencing the experiment. Therefore, all these 9 cows were considered eligible for inclusion in the control group based on their serology results. All cows in the treatment group were also diagnosed as seronegative before commencing the experiment based on the results of the GDP test. Of 3 cows in the treatment group, 2 cows became infected (A×, A××), as indicated by seroconversion within A× days. Therefore the data of the cow that did not become infected was excluded from the statistical analyses. The mean time from intranasal inoculation to seroconversion was A×± A× days (n=3). Of 3 seroconverted cows, three showed seroconversion in the fifteenth day after exposure and two cows had seroconverted by the eighteenth day. Therefore the sera samples on the second, fourth, sixth, eighth days after virus inoculation. The virus was isolated from 3 cows on day A× after inoculation with a peak viraemia of A× log TCID/ml of serum and the titer of the virus in the remaining cows were not detectable. In addition, no virus was isolated from the frozen unfertilized and degenerate embryos. In Experiment II, the two inoculated cows had a detectable viremia (≥ A× mm) on the day of AI for control and infected groups was A×, A× ± A×, respectively (p< A××). Cows in the control group, had A× corpora lutea (detected by rectal palpation), whereas cows in the infected group had a total number of A× corpora lutea on their ovaries on day A× after AI, with a mean (±SE) number of A×, A× and a range of A× to A× corpora lutea. The total of transferable embryos collected from the control and pestivirus infected cows was A× and A×, respectively.

**Embryo culture:** Of 7 morologically normal morula/blastocysts in the control group, 3 (A××) were developed to hatched blastocyst after A× h. culture while of seven embryos in the infected group, only 1 embryo hatched (A×××) after A× h. culture.

**Experiment II**

**Histopathological evaluation of the ovaries:** On slaughterhouse inspection (day A× after superovulatory-induced oestrus), the proportion of grossly normal corpora lutea was significantly (p< A××) greater in the control cows (A××; n=A×) than detected by the degree of paint loss and secondary signs of oestrus.

A composite summary of the superovulatory response is given in Table 1.

a, b, c, d: Means with different superscripts between columns show a significant difference (p< A××).
in the infected cows (\(\gamma^{\alpha}; n=5\)). The mean (±SE) number of unovulated follicles \(\geq 3\) mm in diameter present on the ovaries of the control cows were \(\gamma^{\alpha} \pm \delta^{\alpha}\) compared to \(\gamma^{\alpha} \pm \delta^{\alpha}\) for the infected cows. The ovaries of the infected cows contained fewer normally developed corpora lutea (crown \(\geq 1\) mm) and a greater number of unovulated follicles, many of which were partially luteinized (Figure 1). Histologically the corpora lutea in the ovaries of the control cows slaughtered on day 7 after oestrus were normal, composed of solid luteal tissue. However, many corpora lutea in the ovaries of infected cows had a hypoplastic or atrophic wall and a comparatively large fluid filled central cavity. Even the relatively normal corpora lutea in the infected cows were smaller with a thinner layer of luteal cells and a larger central cavity compared to the corpora lutea in the ovaries of the control cows. Infiltration by mononuclear cells was evident in the wall of some of the unovulated luteinized follicles but minimal or absent in the others.

**Figure 1:** Cross sectional appearance of the superovulated ovaries of a control (A) and a pestivirus infected cow (B) slaughtered on day 7 after superovulatory induced oestrus. Note the well formed corpora lutea in the control cow’s ovaries and the thin walled corpora lutea in the ovaries of the pestivirus infected cow. Also, the diameter of corpora lutea in the infected cows is smaller than in the control cows’ ovaries.

**Immunohistochemistry findings:** In sections from the infected cows, bovine pestivirus antigen was detected focally in the granulose cells of apparently intact mature Graafian follicles as well as more uniformly in granulose cells and infiltrating macrophage in follicles with obvious pathological changes. Antigen positive follicles with or without apparent lesions were often found adjacent to uninfected follicles (A). Virus antigen was present in degenerate, necrotic and detached granulosa cells (A, B) as well as in mononuclear cells, mainly monocyte-macrophages, infiltrating the interstitial parenchyma (arrow heads) as well as the follicles (B). Formaldehyde-fixed, paraffin-embedded tissue sections were labeled with a monoclonal antibody specific for nonstructural protein \(\gamma\) (NS\(\gamma\)). The reaction was visualised using AEC-substrate (red label), and counterstained with hematoxyline. N= normal uninfected follicle, I= bovine pestivirus infected follicle. Bar=\(\gamma\)\(\mu\)m in A and \(\delta\)\(\mu\)m in B.

**DISCUSSION**

The superovulation procedure used in the present study maximized the number of follicles at risk of pestivirus infection. Data obtained from the present study concerning effectiveness of intranasal inoculation are comparable with the findings of Cook et al \(\gamma\)\(\delta\)\(\alpha\)\(\gamma\)\(\gamma\) in that the intranasal inoculation can be considered as one of the effective methods of experimental induction of pestivirus infection. The results of the current study show a significantly higher mean number of the ovulatory
sized-follicles (≥1 mm in diameter) in un-infected control cows on day of AI comparing to that of the pestivirus-infected cows on the corresponding day. Similarly, a lower mean number of ovulatory-sized follicles was observed in superovulated Holstein heifers when underwent an intranasal infection during the period of final growth of preovulatory follicles compared to uninfected control Holstein heifers (Kafi et al ). Further, Grooms et al ( ) reported that the maximum diameter and growth rate of dominant ovulatory follicles were significantly reduced during the two oestrous cycles subsequent to infection of seronegative cattle with a non-cytopathic bovine pestivirus isolate. A lower plasma oestradiol- concentration was observed in the period of the first dominant follicle of post-oestrus in pestivirus infected cows (Fray et al ). The results of the current study and the above-mentioned studies show that pestivirus infection adversely affects on normal development of preovulatory follicles in Holstein dairy heifers and cows.

A significantly lower number of ova/embryos recovered from the pestivirus infected cows comparing to that of control cows in the current study. This could be attributed to the lower number of ovulatory-sized follicles on day of oestrus in the infected cows. The ovulatory-sized follicles in the infected cows either did not ovulate and then regressed or became luteinised-unovulated follicles by day after AI. This explanation is strengthened considering the results of our previous studies that showed an ovulatory disturbance (Kafi et al ) associated with a disturbance in preovulatory LH surge (McGowan et al ) in pestivirus infected heifers comparing to that of the uninfected control heifers. The reason for a low number of transferable embryos recovered from the control cows in the current study could be the long half-life of eCG in blood (Boland et al ). This has been shown to produce a highly oestrogenic uterine environment which this, in turn, may adversely affect the quality of developing embryos (Schams et al ; Boland et al ).

The results of the embryo culture in the present study showed a significantly lower percentage of hatched blastocyst of the embryos collected from pestivirus infected cows comparing to that of the embryos collected from the uninfected control cows. Although it has been shown that blastomeres are permissive to pestivirus infection (Vanroose et al ), there is no compelling evidence to indicate that blastomeres from in vivo-derived, zona pellucida-intact embryos can be infected with non-cytopathogenic BVDV. Studies in vitro have failed to show conclusively that non-cytopathogenic BVDV compromises embryo development directly (Zurovac et al ; Stringfellow et al ). Although the number of morula/blastocysts cultured in Experiment I of the present study was not high enough to make a strong conclusion however, the lower hatching rate in the embryos recovered from the pestivirus infected cows compared to that of the uninfected control cows shows that bovine pestivirus may adversely affect the normal development of the embryos. This finding is consistent with those of Bielanski and Dubuc ( ) who reported a lower in vitro developmental competence in the oocytes collected from experimentally pestivirus infected heifers.

The results obtained from the experiment II of the present study could help to explain the lower ovulation rate in pestivirus infected cattle. Pestivirus antigen was detected in granulosa cells and infiltrating macrophages in follicles between and days after inoculation. Interestingly, there were follicles with extensive virus infection accompanied by destruction of granulose cells next to non-infected and intact follicles. This finding was similarly observed by Brownlie et al ( ) in the ovaries of persistently infected cattle. There is no clear explanation for this peculiar histopathological feature.
In conclusion, the present study demonstrated that pestvirus infection during the period of final growth of preovulatory follicles results in a disturbance in ovulation leading to abnormal development of corpus luteum in multiparous dairy cows. Further, results of embryo culture of the present study showed that superovulated dairy cows infected with pestvirus during the period of final growth of preovulatory follicles may produce embryos that are not developmentally competent.

Acknowledgements

We would like to thank Professors P.D. Kirkland (Elizabeth Macarthur agricultural Institute) for allowing us to perform serology and virology examinations of the samples and also sincere thanks to Professor Ed Dubovi (Cornell University) for his kindly providing us the monoclonal antibody for the immunohistochemistry.
